Descartes proposed that all observable human behavior could be divided into 2 categories, the simple and the complex. Simple behaviors were those in which a given sensation always, deterministically, produced the same behavioral response. . . . Complex behaviors, in contrast were those in which the linkage between sensation and action was unpredictable and subject to the vagaries of volition. . . . They were produced when sensory data were transmitted from the nervous system to the nonmaterial soul, the soul made a decision about what course of action to undertake, and this volitional command was then passed to the machinery of the body for execution.

From Paul W. Glimcher, 2003, Decisions, Uncertainty, and the Brain

1. Introduction

The state of our understanding of the interaction between pain and the brain is undergoing a veritable revolution, with new surprising observations accumulating at a fast pace. A cursory search in PubMed for the term: “functional AND MRI AND pain AND brain” identifies 875 papers and 138 reviews. We will not go over this material. Here we highlight ideas regarding the transition of the human brain from acute to chronic pain, based primarily on human functional and anatomical brain imaging studies, where we examine current advances in understanding, possible underlying mechanisms, and discuss implications regarding both the properties of the brain, our understanding of pain, and possible novel therapeutic venues.

Aristotle categorized pain as an “affect,” separating it from primary senses. On the other hand, Descartes illustrated a skin to nerve to brain pathway for the transduction of a burning stimulus on the skin to a pain qualia. This dichotomy persists in the discussion of pain mechanisms to this day. It has been exemplified by opposing positions by classic pain scientists such as Hardy and Beecher, and Ed Perl, Ron Melzack, and Pat Wall. Pat Wall in fact used Descartes drawings as a means of ridiculing the reductionist attitude that most pain scientist exhibited at his time and that continues unabated in current research. The IASP definition of pain (<http://www.iasp-pain.org/>) ducks the issue by marrying the 2

concepts together, and by also stating that pain is subjective and may not be related to an actual injury. This position, however, poses a new quandary: if pain is subjective and minimally related to a stimulus why, and how, do we study its related brain activity? Similarly, if pain is both sensory and emotional, how well have we fared in disentangling these components in the brain? And how do these modalities differ between acute and chronic pain? We tackle these issues here, attempting to demystify current understanding of the brain in pain by emphasizing mechanistic implications of research in the field.

2. Brain representations for acute pain: how much further past phrenology?

Human functional brain imaging, since its inception in early 1990s, has concentrated heavily on examining brain properties for acute painful stimuli in healthy subjects. This is not surprising, as mapping stimulus–response representations imposes fewer methodological challenges than studying chronic pain [94]; yet there still remain many unanswered critical questions regarding representation/encoding/processing of acute pain in the brain. We will not cover this topic in detail. However, important new concepts are highlighted providing the opportunity to then contrast properties of brain circuitry between acute pain and clinical pain.

A large number of studies have demonstrated a network of brain areas consistently activated with acute thermal, mechanical, and chemical painful stimuli [4,15,100,101,112]. These brain areas, or some sub-set, super-set, of them have been labeled as the “pain matrix” and used as a brain signature for an activity pattern associated with pain. The data reviewed here argue against this notion by indicating that there is no unitary set of brain regions that one can equate to presence of pain. This is especially true for distinct clinical chronic pain conditions that show unique brain activity patterns. Therefore, the spatial patterns seen for acute pain, although consistent across many laboratories and brain imaging paradigms, are only valid in healthy subjects and only for acute pain. Localizing a consistent set of brain regions activated with acute pain has been an important step forward (see, for example, review [20]). However, until we delineate functional roles of involved regions and the temporal dynamics of interactions [5,79], our understanding of this circuitry remains at the level of modern phrenology (brain-based phrenology) and even of epi-phenomenology. Unless the

specificity, causality, capturing of features, and calculations of unique parameters of pain and its spatiotemporal dynamics are identified, the existing “pain maps” provide little more than evidence for responses that may all be unessential, for example, attentional/motoric/autonomic/anxiety/fear shifts in the presence or in anticipation of impending pain [1].

Correlation to stimulus parameters, primarily its intensity, is 1 metric used to differentiate between brain regions activated with acute pain. However, this leads to a majority of brain regions that are identified to be active in acute pain showing such correlations [85,25]. Yet, Coghill et al. used this approach and were able to identify that brain regions encoding painful stimulus intensities are primarily in the hemisphere contralateral to the stimulated body site [24]. The same group examined the discrimination between stimulus localization and stimulus intensity to further subdivide the brain areas related to acute pain [80], and advance the exciting notion that pain, similar to vision and audition, may also comprise a ventral, in this case, intensity coding stream, and a dorsal, spatial localization stream. We as well as other groups have emphasized the need to identify brain activity relative to the subjective perception of pain [27,64,41,59,68]. After all, we all accept that the brain should reflect perception, and in fact the classical view has been that even peripheral primary afferent nociceptors show a close correspondence in their stimulus–response curves to the psychophysical power function that one observes for thermal or mechanical painful stimuli in humans. On the other hand, group averaged afferent activity seems to fail to correlate with ratings of perceived pain [71]. Thus, it is not clear whether there even exist differences in brain activity for stimulus presentation versus subjective perception, and it is possible that brain activity based on stimulus or perception parameters are both looking at the same brain regions with minor changes in interpretational emphasis. Thus, we arrive at a fundamental question: namely, is subjective perception of pain distinguishable from brain regions better representing painful stimuli? If the distinction exists, then the latter areas would be more properly labeled as nociceptive regions, while the former would be pain-perceptive areas. This distinction in fact would correspond to Descartes idea of the difference between the simple and complex categories, with the simple executed by sensory pathways which must be integrated with the subjectivity (Descartes’ soul) to give rise to perceived pain.

2.1. Distinct brain areas can be called nociceptive or perceptive

Implicit in all studies in which brain activity is related to stimulus parameters is the notion that these parameters are uniformly reflected in perceived subjectivity of pain, and of course in a group average this is certainly correct (see, for example Fig. 1 in Baliki et al. [9]). Yet, when one asks subjects to continuously rate their perception of pain, for a constant thermal stimulus applied to the same body site in all subjects, we observe large interindividual variability of responses [9] (Fig. 1, top panel). Furthermore, based on differences in stimulus properties, there are marked effects of adaptation and sensitization on pain dynamics [51]. This observation per se indicates that brain imaging studies, where individual subjective differences in perceived pain are not taken into account, a large portion of the brain response variability is directly due to across-subject differences in perceived pain. On the other hand, variability of perceived pain in contrast to the constancy of the stimulus provides the opportunity of differentiating between brain areas that better correlate with each, that is, distinguishing between representation of physical stimulus parameters, nociceptive regions, from regions better reflecting subjectivity or perception of pain.

Parts of anterior cingulate (ACC) show a high incidence of activation in pain tasks [4]; as a result, ACC is commonly dubbed as the

main brain region signaling pain, or emotional pain. Yet single unit recordings from the region in awake human beings do not show nociceptive-responsive cells. Instead, ACC neurons seem to respond to cognitively demanding situations, including those with emotional valence [29], implying that the region is more involved in anticipation of salient conditions. It is also important to note that a large number of nonpainful tasks activate various portions of the cingulate cortex. Similar to the ACC, the insular cortex shows a very high incidence of activation in pain tasks [4], and parts of the region are dubbed signaling either sensory or emotional/affective properties of pain. Electrical stimulation of posterior parts of the insula in human beings does give rise to pain-like sensations [68]. In addition, some lesion studies imply that insults to the insula may decrease pain perception [13,88]. A more recent study, on the other hand, shows that unilateral insula lesions increase, rather than decrease, thermal pain responsiveness [99]. Similarly to ACC, insula is also activated for a very large number of nonpainful tasks [58].

Given the importance of the cingulate and insula in pain perception, we analyzed these regions for spatial segregation along the dimensions of nociceptive representation versus pain perception, using published data [9]. Fig. 1 (bottom panel) shows the spatial segregation of the 2 brain regions along stimulus–perception representation. We observe that the anterior portion of the cingulate and the posterior insula better reflect pain perception, whereas large portions of both structures are mainly related to thermal stimulus properties.

2.2. Strength of relationship between brain activity and pain consciousness

The fact that we can localize brain areas that preferentially encode subjective perception of pain first implies that the transformation from stimulus space to subjectivity is a cortical process, the details of which remain to be understood. It also raises the important question of the extent to which this region reflects pain subjectivity, which also impinges on issues regarding consciousness and pain. To date, human beings lack physical theories of consciousness. As a consequence, the best evidence we can advance of relationships between consciousness and biological processes can be correlative. The strength of evidence for the portion of insula better related to pain perception is shown in Fig. 2. The figure illustrates that the brain activity, as determined by functional magnetic resonance imaging (fMRI), in this insular region reflects the magnitude of subjective pain *every time* a participant indicates that individual’s perceived magnitude of pain, with a linear correlation between brain activity and magnitude of subjective perception. Therefore, there is a very tight relationship between this area of the brain and pain consciousness. Besides a second more lateral extension of the region in the prefrontal cortex, no other brain region has shown such a representation of subjective pain. On the other hand, as Fig. 2 shows, the region also faithfully reflected brain activity for rating the magnitude of visual stimuli. Therefore, we can state that this area is unique in reflecting pain subjectivity but is not specific to any particular sensory modality. We have thus proposed that the area is instead specialized in extracting subjective magnitudes in general [9], and argue the notion that the insular stream of information processing, in analogy to the dorsal and ventral visual streams that encode “where” and “what” may be extracting a signal in relation to subjective “how much.” Thus we propose that conscious perception of pain is the end-product of the transformation of nociceptive information to a magnitude, achieved in a brain region that also extracts magnitudes for visual lengths, and in analogy also perhaps visual brightness, auditory loudness, olfactory pungency, etc. – relationships that remain to be systematically studied.

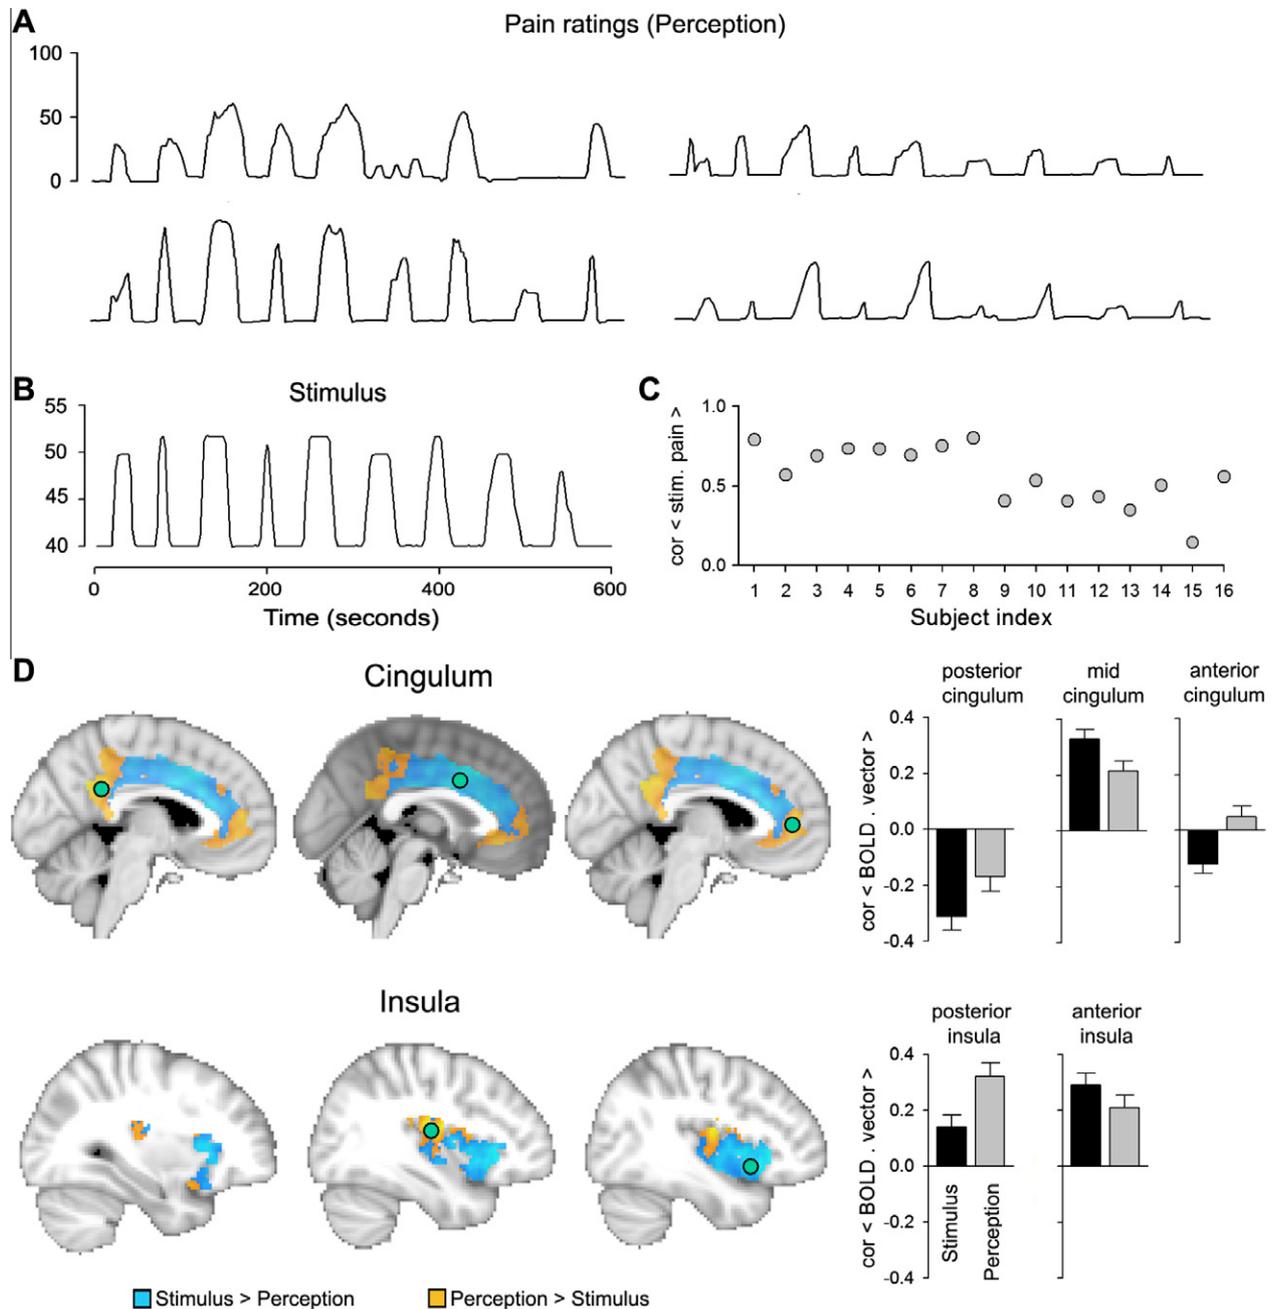

Fig. 1. Segregating the cingulate and insular cortices along the stimulus and subjective perception dimensions for acute thermal pain. (A) Variability of subjective ratings of pain is illustrated for 4 subjects. (B) Temporal and intensity properties for a constant thermal stimulus that was applied to the skin on the back. (C) Variability of correlation between the stimulus and ratings for the 16 subjects in the study. (D) Contrasting cingulate gyrus and insula activity between stimulus and perception identifies statistically significant regional differences in each area along these dimensions. Green circles are regions where activity was extracted and correlated either with the stimulus or individual subject perceptions, corresponding bar graphs are in the right, which indicate the sign and extent of difference between representation of stimulus and perception. Anterior cingulate and posterior insula are regions best related to pain perception. All data are derived from the study described by Baliki et al. [9].

2.3. Temporal transformation of pain representation: from anticipation to perception to relief

The fact that pain is processed far more slowly by the nervous system than any of the other sensory modalities makes it an ideal sensation with which fMRI brain activity can be segmented in the time domain to component circuitry that process incoming information and spatiotemporally extract specific features. Yet another fundamental property of pain is its salience, which simply corresponds to the common experience that the prospect of impending pain or the experience of pain both engage one's attention, forcing

a motivational state in which the subject needs to make decisions as to the immediate future. Of course, proper anticipation of impending pain is fundamental for survival and must thus be closely linked to reward, motivation, and decision making [33]. Brain activations to signals anticipating impending pain has been studied by a number of groups [12,19,82–84,107]. For the most part, these studies concentrate on examining distortions of brain activity for the stimulus in the presence of anticipatory cues, as well as brain responses to the cue itself. In a recent study, we demonstrated that nucleus Accumbens (NAc) signals anticipation of pain perception even when the stimuli are applied randomly and in the absence

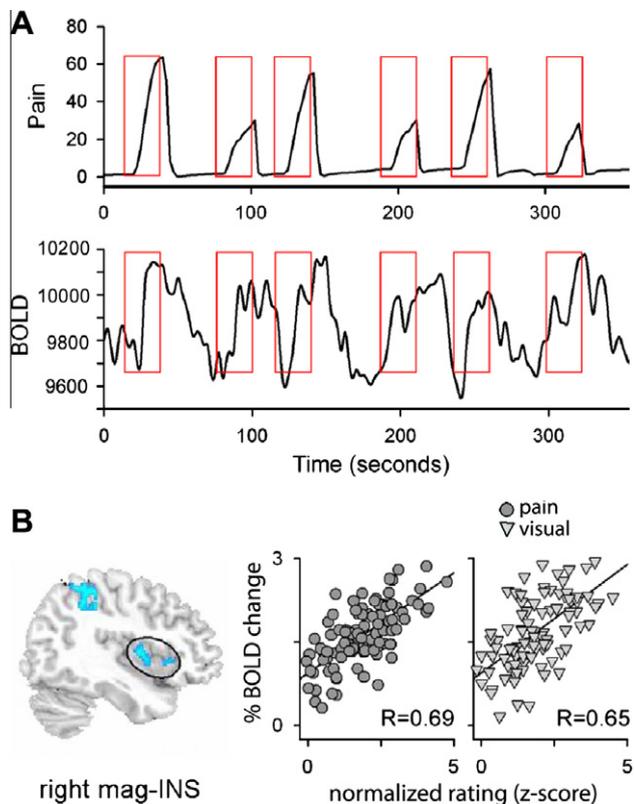

Fig. 2. Insular region that reflects pain perception shows a one-to-one relationship with each epoch where pain is reported. Moreover, this area also just as faithfully encodes perceived magnitudes for bars displayed visually. Thus, the brain area accurately reflecting pain subjectivity seems to be encoding magnitudes in general and thus lacks specificity. (A) Illustration of the method used for generating the scattergrams in (B). For each epoch of perceived pain, the magnitude of peak pain rating is extracted and correlated to the peak fMRI BOLD activity identified within the thermal stimulus time window (illustrated in red boxes). (B) Left figure shows the region of the insula that encodes perceived pain and perceived magnitude of lengths of visual bars (circled region is right magnitude related insula, mag-INS). First scattergram is the epoch-by-epoch pain perception to BOLD relationship, across all subjects. Second scattergram is for the visual magnitude-rating task. Correlation coefficients are indicated and closely match for both sensory dimensions. Data and figure adapted from the study described in Baliki et al. [9].

of any external cues [11]. At the start of an unpredictable painful thermal stimulus, NAc activity captured the rate of change of the stimulus applied on the skin, an activity that preceded the stimulus itself as well as the related perception. In Fig. 3, we reanalyze those data by contrasting brain activity among 3 epochs, anticipation (early activity at start of stimulus), perception, and relief (late activity at stimulus end). The results indicate segregated networks that preferentially are involved in each epoch, with anticipation engaging NAc, mid-cingulate, and anterior insula; perception activating anterior cingulate, mid- and posterior insula, and large portion of dorsal striatum; and pain relief engaging brainstem activity, especially the periaqueductal grey (PAG). The brain networks identified in Fig. 3 complement those illustrated in Fig. 2, in that regions involved in anticipation are also regions that better relate to stimulus, rather than perception, encoding. The PAG activity is similar to earlier brain imaging observations of the region signaling pain relief [31,32,110] and consistent with the region being involved in descending anti-nociceptive modulation, as repeatedly shown in animal studies. The main point of Fig. 3 is the illustration that distinct portions of brain regions known to be involved in acute pain show a specific spatiotemporal evolution, as these areas extract distinct types of information in relation to the nociceptive stimulus and ensuing subjective perception of pain.

The networks identified in Fig. 3 were determined using a priori vectors that would define the types of information that can be extracted within a given time window. An alternative approach to determining the spatiotemporal evolution of information flow during pain perception would be to interrogate the properties of brain areas identified to be active during the task. The latter approach was used in a recent study [9], and the main outcome is illustrated in Fig. 4. Fourteen brain regions were observed active during rating of acute thermal pain. The thermal stimulus peak (after convolving with fMRI hemodynamic function) on average preceded the peak perception by approximately 8 s. Within this time window, one could then examine the sequence of activations across the 14 brain areas by determining each region's peak activity. Moreover, as the shape of the brain activity differs between brain regions, its similarity can be tested to the stimulus and perception. These 2 parameters provide a 2-dimensional space within which the 14 brain regions can be localized. Fig. 4 shows that the amygdala and mid-ACC peak before the stimulus itself peaks. Thus, the mid-ACC, now together with the amygdala, is again showing an anticipatory response. We then observe a sequence of activations in brain regions that are consistent with being more nociceptive, including the thalamus, dorsal striatum, supplementary motor area, and nociceptive insula, all of which peak just after the stimulus peaks and their activity patterns show better similarity to the stimulus. On the other hand, perception-related magnitude region of the insula peaks much later, just preceding perception, and its activity better correlates with perception. Thus we observe a spatiotemporal sequence of activity that is consistent and complementary to the sequence identified in Fig. 3. The information transformation from the NAc, amygdala, and mid ACC, to the thalamus and nociceptive insula, and finally to perceive/magnitude encoding insula closely corresponds to Coghill's notion of a ventral stream specialized in processing intensity of painful stimuli [80]. Thus, detailed information processing steps can be observed and parceled in the human with fMRI, especially for acute pain where the sequence of transitions from stimulus to perception is slow enough to enable such analyses.

2.4. Medial and lateral pain systems and emotional and sensory representations

Two elegant studies first established that human brain activity may be subdivided along emotional and sensory components [53,86], in which mid-ACC was identified as being modulated by affect and primary somatosensory cortex by sensory properties of pain perception. Complementary evidence along these lines were studies by Zubieta et al. [111], who showed distinct brain activations correlated to the sensory or affective components of the McGill Pain Questionnaire (MPQ). These observations build on notions that date to the beginning of the twentieth century when Sherrington [97], in 1906, advanced the idea that pain has both sensory and emotional qualities, and Head and Holmes [52], in 1911, distinguished between protopathic and epicritic pathways. Ideas that were further propounded in the 1960s [69] regarding a medial and lateral spinothalamic pathways, with the former being involved in affect and the latter in sensory encoding. Yet this concept has not progressed much further, and the notion of segregating brain activity for acute pain along these 2 dimensions remains relatively weak. For instance, it should be noted that many spino-cephalad pathways show considerable crosstalk [42,49]. A major difficulty is inherent in the IASP definition, stating that pain is always unpleasant, based on the fact that intensity of pain and magnitude of unpleasantness of pain are almost always highly correlated with each other. Therefore, rendering distinctions between these components is difficult. Despite the weak evidence regarding segregation of sensory and affective mechanisms of pain, authors almost arbitrarily assign the tag of

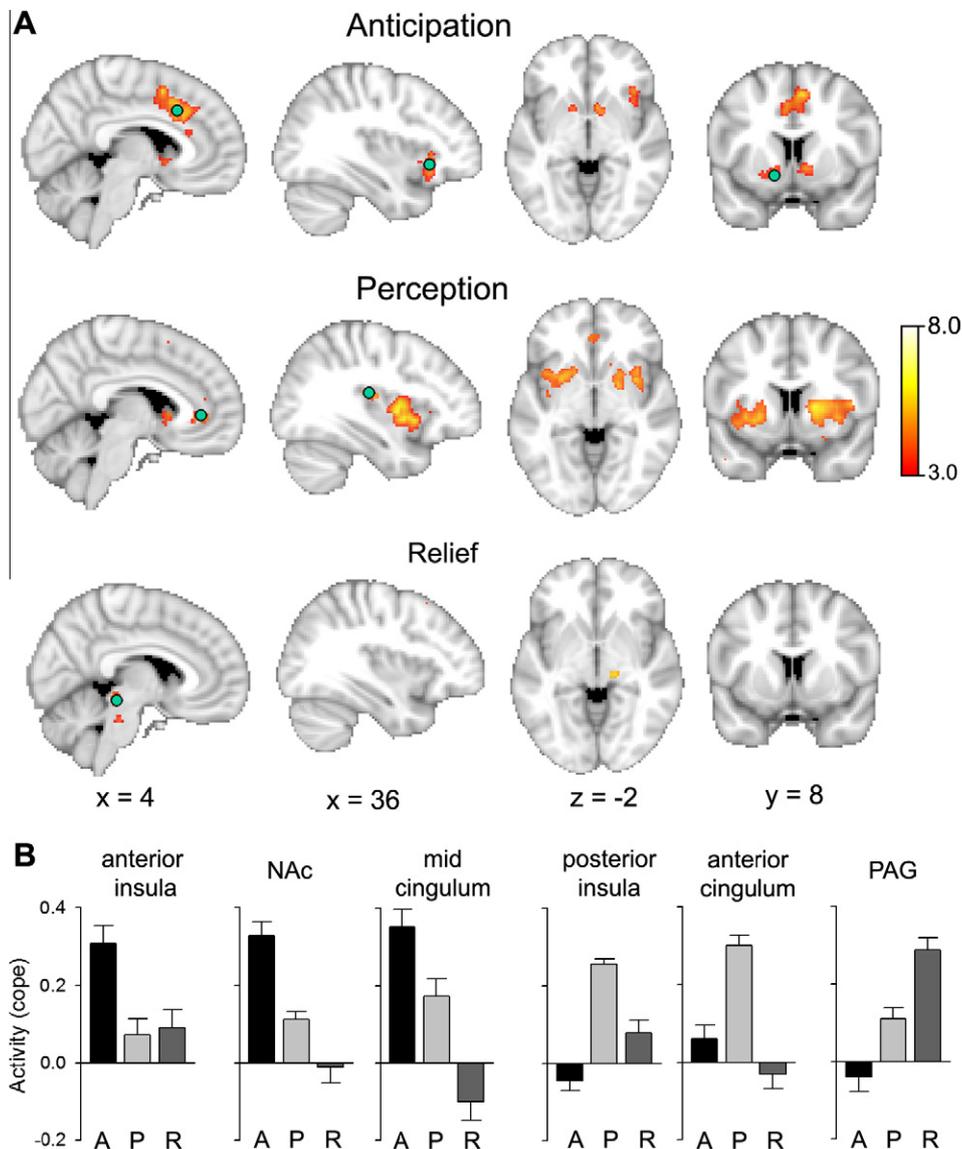

Fig. 3. Segregating brain activity for acute thermal pain perception between anticipation, perception and pain relief identifies distinct networks sequentially activated during perception of acute pain. Three vectors separated in time were contrasted for a thermal painful stimulus that was a randomized sequence of stimuli where intensity duration and inter-stimulus intervals were not predictable. The anticipation vector identified increased activity preferentially related to only the start of the stimulus; while perception was identified by subjective ratings of pain; and relief period was identified for increased activity in the time window when the stimulus was returning to baseline. (A) Three separate and complementary networks are identified. (B) Differential activity for the 3 phases of pain perception is illustrated for indicated regions (green circles in A). A = anticipation, P = perception, R = relief. Data are derived from the study described in [11].

sensory or affective to various brain regional activations, relying mostly on the classical anatomy that shows that lateral thalamic regions project to primary and secondary somatosensory regions, whereas medial thalamic projections target limbic and frontal cortex. The case for insular activity is worst, as even the anatomical guide fails for this brain region.

It has recently been argued that an alternative approach to distinguishing between sensory representation and affect would be to examine the brain from the viewpoint of motivation [33]; with this approach, we were able to identify that NAc activity not only signals anticipation of impending pain but seems to also calculate the reward value of pain relief at stimulus cessation by integrating information from the magnitude region of the insula in healthy subjects [11]. The motivational approach provides the opportunity to test the emotional valuation of pain by behavioral and decision-making measures independent of sensory encoding. Yet this line of work, especially for pain, remains in its infancy.

2.5. Overall summary

The section above illustrates the brain dynamics for acute pain. The brain regions involved and their properties provide a background relative to which we can contrast brain activity for clinical pain conditions.

3. Functional properties of the brain in chronic clinical pain

Clinically, the most relevant conditions in which human brain imaging can have a substantial impact are chronic conditions, as they remain most poorly understood and minimally treatable by existing therapies. The IASP definition of chronic pain is either based on duration of pain persisting past an inciting event (arbitrary number of 3–6 months) or pain extending past the healing process from the initial injury. We have commented on the inadequacy of this definition [3] and also proposed possible

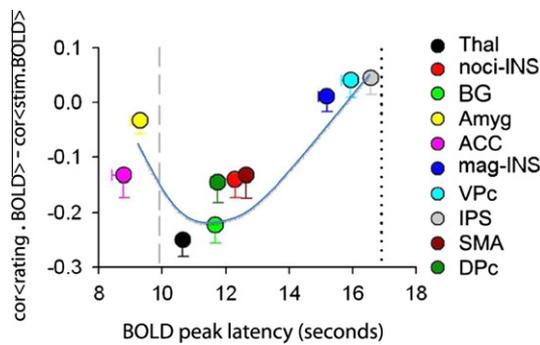

Fig. 4. Temporal sequence of brain activity for thermal painful stimuli determined in relation to anticipated peak for the stimulus (vertical line at 10 s from stimulus start) and actual reported peak of pain perception (vertical line at 17 s). Vertical scale is similarity of brain activity shape to the stimulus and perception shapes (negative values are better correlations to stimulus shape while positive values are better correlations to perception, determined for specific BOLD activity extracted for all regions listed on the right). The anterior cingulate (ACC) and amygdala (Amyg) peak at times prior to the stimulus peak, implying that these regions are more related to anticipation of impending pain. The thalamic activity (Thal) peaks just after the stimulus and best reflects stimulus shape. Nociceptive insula (noci-INS) and magnitude insula (mag-INS) are segregated by time and shape similarity, reflecting their respective functional labels. The blue curve approximates the brain spatio-temporal evolution of nociceptive information being transformed into subjective consciousness of pain. BG = basal ganglia; DPc = dorsal prefrontal cortex; IPS = inferior parietal sulcus; SMA = supplementary motor area; VPc = ventral prefrontal cortex. Adapted from [9].

extensions based on the recent brain imaging evidence [2]. The challenge in studying clinical chronic pain conditions is to distil the relevant pain from other confounds and, relate brain activity directly to this clinical pain. As most chronic pain conditions remain minimally controlled by therapeutics, and as therapeutics, especially pharmacological approaches with central action, will also interfere nonspecifically with brain activity, there remains little leeway of options for such brain imaging studies. A number of recent reviews summarize fundamental findings regarding brain activity and anatomical changes in chronic pain [3,61,100]. Advances in understanding complex regional pain syndrome (CRPS) in the context of cortical reorganization has also been reviewed [95].

3.1. Specificity of brain activity relative to spontaneous fluctuations of the pain of chronic back pain

Even though many chronic pain patients show signs of allodynia and/or hyperalgesia to various stimuli applied to the skin, by far the most prominent exhibition of chronic pain is uncontrolled, ongoing pain in the absence of any external stimulation. We have uncovered that this spontaneous pain has characteristic fluctuations (in the scale of seconds to minutes) that are distinct for different types of chronic pain and that cannot be mimicked by healthy subjects pretending to have pain [35]. Therefore continuous ratings of these fluctuations can be used as a tool to study spontaneous pain-related brain activity. In fact, given that continuous ratings can capture spontaneous pain, the subjective perceptual rating of pain becomes a universal tool with which one can tease out specific pain components, as the same exact approach can be used to rate a stimulus, such as described above for thermal pain, it can also be used to provoke clinically relevant pains, such as localized allodynia and hyperalgesia, as well as spontaneous pain (after properly correcting for motor, cognitive, and attentional confounds). We have used this technique to identify brain activity for spontaneous pain in chronic back pain patients [8]. The surprise was that the brain region best reflecting high magnitude of back pain was localized to the medial prefrontal cortex (mPFC),

extending into anterior ACC, a region not anticipated by acute pain studies. Additionally, brain areas observed for acute pain, like portions of the insula and mid-ACC were only active transiently and only when the back pain magnitude was on the increase. These results are exciting because, for the first time, we are able to observe brain activity reflecting the subjective perception of the pain that chronic back pain patients come to the clinic to complain about (or an objective marker for the Cartesian soul of back pain). We interpret the transient activity as a nociceptive signal from the periphery, which then is converted into a sustained emotional suffering signal in mPFC.

These observations are based on patients' own ratings in which the experimenter has no control and cannot discern whether the patient is actually reporting anything factually related to the phenomenon of interest or is simply rating whatever comes to that individual's mind. This in fact is a major weakness of many similar brain-imaging studies and requires an alternative approach to identify veracity of the results. We overcome this limitation by performing an across-subject correlation analysis examining the relationship between intensity and duration of back pain to brain activity. Fig. 5 shows that mPFC activity tightly correlates with amount of pain the patients reported just before starting brain scans, and also that the insular cortex activity correlates with the number of years each subject had been suffering from back pain. Thus, the 2 fundamental clinical properties of the back pain are captured at a high enough correlation strength that we can state that, looking at these brain regions in other such patients, we should be able to predict their back pain magnitude and duration within 20% error. These findings were reproduced in a second group of chronic back pain patients and were also compared with brain activity for rating a thermal painful stimulus applied to the skin on the back. When insular and mPFC activity was examined in these patients and in healthy subjects, we found that mPFC activity was related to spontaneous pain but not with thermal pain,

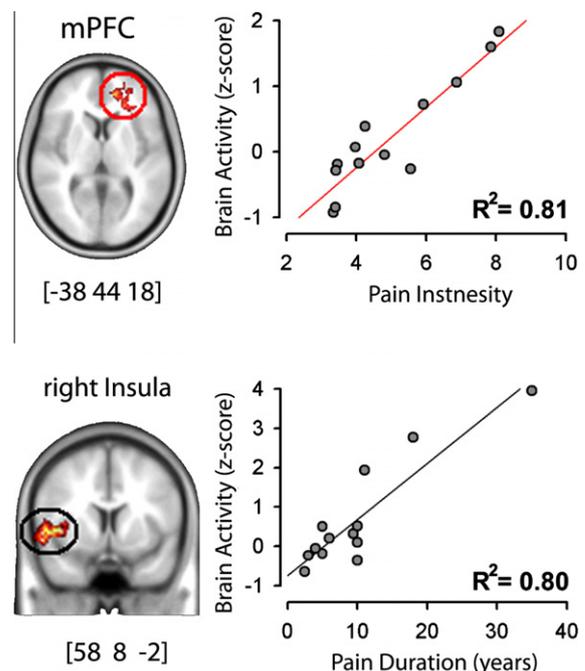

Fig. 5. Brain activity for rating spontaneous fluctuations of back pain in chronic back pain patients show a strong correlation with intensity and duration of the condition across all participating patients. The observed correlations are strong enough that we can assert that the task can be used to predict intensity and duration of chronic back pain in individual subjects within an error of 20%. Figure adapted from [8].

while the insula activity was related to the thermal pain but not spontaneous pain. With this technique, we were able to demonstrate a double dissociation for representation of perceived magnitudes between acute thermal pain and spontaneous chronic back pain.

Thus we can assert that, at least in this group of chronic pain patients, different brain areas encode the perceived magnitude for distinct types of pain. The prevalent expectation for brain activity in chronic pain is a sustained or enhanced activation of the brain areas already identified for acute pain. This view is partly implied by the chronic pain definition and by notions of specificity theory or labeled line theory of pain (where supraspinal organization and representation of pain is assumed to be through fixed and immutable routes). This is exactly what we do *not* see. Instead these results imply that functional anatomy or physiology or some combination of both have changed in the brain of chronic back pain patients. Below we elaborate on underlying possible mechanisms for this reorganization.

It is also important to remember that the close relationships between fundamental properties of back pain and activity in mPFC and insula are correlational, and that both mPFC and insula respond to a long list of cognitive and emotional states. Thus, the phenomenon of observing these areas activated and interpreting them as evidence for existence of pain is false. In fact, even taking into account the underlying dynamic network is most likely a poor (linear) underestimation of the total brain state that constitutes such a condition, and we suspect that current concepts of the brain encoding *any* given perceptual/cognitive condition remains very limited.

3.2. Specificity of brain activity across multiple chronic pain conditions

As explained above, the approach of continuous rating of fluctuations of pain may be applied for a variety of conditions. Besides back pain, we have now studied brain activity for spontaneous pain in postherpetic neuralgia and its modulation by a lidocaine patch therapy [39], in chronic pelvic pain patients (manuscript in preparation), and in osteoarthritis (manuscript submitted); in addition, in post-herpetic neuralgia we have examined brain activity for tactile allodynia, and in osteoarthritis for mechanical painful stimulation of the arthritic knee. The brain activations observed in these various pain groups are summarized in Fig. 6A. What is common between all the brain maps is the presence of pain. Thus we can ask the simple question as to what brain areas are commonly active between these conditions, which would identify the center of pain perception, irrespective of the type of pain. Unfortunately the conjunction across all results in an empty map, suggesting that distinct clinical pain involve unique brain regions. The figure also illustrates that thermal or mechanical acute painful stimuli in healthy subjects or in chronic pain, in this case osteoarthritis, they essentially activate very similar regions. On the other hand, brain activity for spontaneous pain seems to involve different brain regions for distinct chronic pain groups. To better illustrate this point, we show group-average magnitude of brain activity in 2 limbic brain areas and 2 sensory areas and for a variety of groups and stimuli, illustrating a complex gradient of brain activity across these brain areas that distinguishes between stimulus types and chronic pain types.

Fig. 6B addresses the issue of specificity of brain activity for various pain conditions from the viewpoint of a single brain region and in relation to individual subjects' activity. As mPFC is activated for spontaneous fluctuations of chronic back pain, we interrogate its activity across a number of other acute and chronic pain conditions, and observe that it has a very high accuracy in distinguishing chronic back pain from other chronic pain conditions and from acute pain in healthy subjects.

3.3. Presence of chronic pain interferes with brain processing in general

Above we concentrated on the evidence for specific brain activity signatures for acute and chronic pain. Given the salience of pain, one expects that presence of pain will distort brain processing of other information. Interaction between acute pain and sensory and emotional distractions has been repeatedly documented [62,63,105,106]. Here we briefly review the accumulating evidence regarding chronic pain. Our first main observation of chronic pain state disrupting brain processing was observed in postherpetic neuralgia patients. We have studied these patients before and after lidocaine patch treatment, in an open-label study in which spontaneous pain was significantly decreased with the therapy. As the patients rated their ongoing pain on a visual bar, we tested the idea that whole-brain activity may be modulated by the intensity of the chronic pain for both the pain and non-pain tasks [39]. Fig. 7 shows that posterior parietal activity is generally decreased whereas prefrontal medial and lateral activity is increased for both task with intensity of this pain. Parietal decreased activity suggests that brain attentional networks are attenuated by the chronic pain, whereas the frontal increased activity may be due to cognitive and emotional enhanced processing. Yet, the observed brain regions modulated are vast and complex, and undoubtedly other processing abilities are distorted in these patients. In a second, more systematic approach to the question, we examined brain activity differences between healthy subjects and chronic back pain patients for rating the fluctuations of a visual bar. Performance was matched between the groups and increased brain activity also matched. On the other hand, decreased activity was significantly different [10]. As the brain regions in the decreased activity corresponds to a specific brain network, default-mode network, we tested the balance between positively and negatively correlated networks and could show that the overall balance of these networks is shifted in the chronic back patients. These results suggest that the brain in the resting state (brain activity in the absence of subjects doing anything specific) should also be distorted in chronic pain conditions, and this in fact has now been asserted for a number of clinical conditions [21,22,66,75]. The study by Malinen et al. [66] is noteworthy, as the authors extend the observations of distorted resting state networks to also report that the frequency of brain activity during rest is higher in the insula and anterior cingulate in chronic pain patients (Fig. 8). We have been able to replicate the latter result in chronic back pain patients and additionally to demonstrate that the increase in power at the high-frequency range is related to the characteristics of the back pain (manuscript in preparation). It should be mentioned that studying chronic pain patients' brain during rest promises to be yet another fruitful venue that should inform us of the global dynamical properties of the human brain in pain. How do such changes come about? Are they specific for different clinical conditions? To what extent are they driven by anatomy, behavior, or peripheral reorganization? And how are they modulated by therapeutics? These are all exciting and addressable questions.

3.4. Chronic pain distorts motivational value of analgesia

Above we concentrated on the evidence for specific brain activity signatures for acute and chronic pain. Here we identify interactions between motivational systems in acute pain and how they are modified by chronic pain. Acute pain plays a protective role in that its presence elicits the motivation to escape or avoid exposure to minimize further damage and its termination provides a sense of relief. Together these processes contribute to predicting the utility and costs of competing goals and in behavioral decisions in the presence of conflict between potential threat and reward.

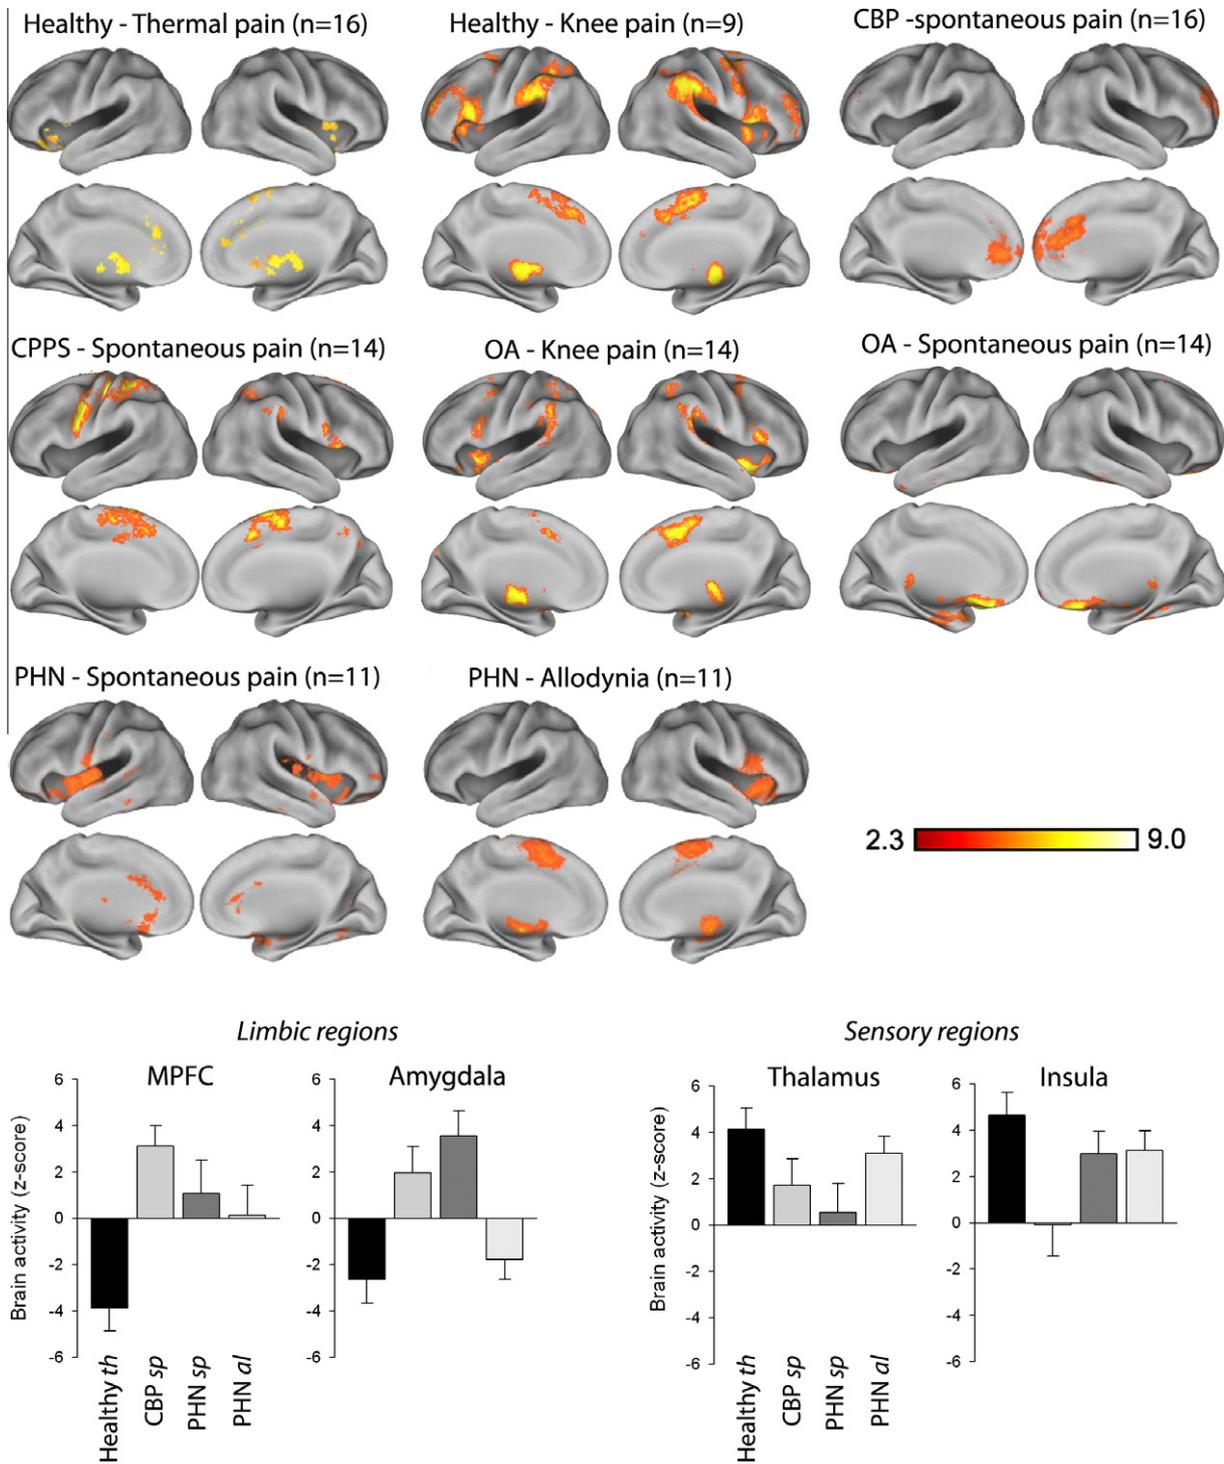

Fig. 6A. Brain activity patterns for various clinical chronic pain conditions. Activity maps: are group-averaged responses for different pain conditions. Activity maps: Thermal pain, knee-pressure-induced pain in healthy subjects, and in osteoarthritis patients (OA) show similar patterns of brain activity, implying that all 3 results correspond to acute pain activity. In contrast, brain activity for spontaneous pain in different clinical conditions (chronic back pain [CBP], osteoarthritis [OA], pelvic pain [CPPS], and post-herpetic neuralgia [PHN]) show different activity patterns, engaging to different extents sensory and limbic brain areas. In PHN, tactile allodynia and spontaneous pain evoke relatively distinct brain regions too. Bar graphs: Magnitude of activity in 2 limbic regions (mPFC and Amygdala) and 2 sensory regions (thalamus and insula) are compared for 4 groups: healthy subjects for thermal pain, Healthy th; chronic back pain patients for spontaneous pain, CBP sp; post-herpetic neuralgia for spontaneous pain, PHN sp, and for tactile allodynia, PHN al). Thermal pain and PHN allodynia show larger activity in the sensory regions, while spontaneous pain in CBP and PHN evoke more limbic activity.

Chronic pain lacks these motivational advantages and instead imposes a persisting stress on these protective and adaptive systems. Only 1 paper has addressed chronic pain from the view of motivated behavior, and the results are surprising and unexpected [11].

We [8,9,11] and Derbyshire et al. [30], in an earlier study, have shown that the perceived magnitude of thermal pain and related

representation of the stimulus and perception do not differ between chronic back pain patients and healthy subjects. On the other hand, a number of studies do demonstrate increased brain activity for mechanical pain in distinct chronic pain conditions [41,43,81]. It is not clear where the discrepancy between these studies lies; is it due to differences in sensory modality tested, ie,

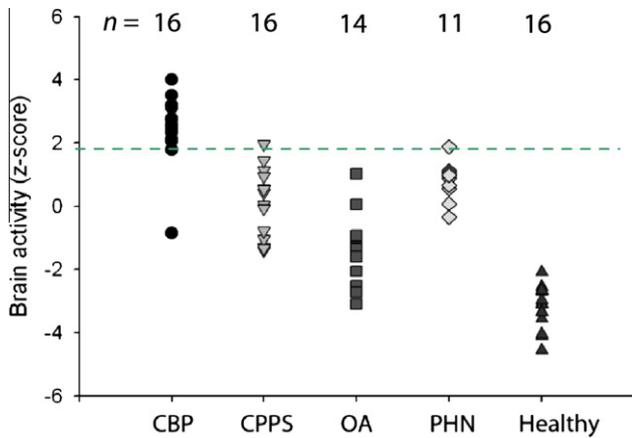

Fig. 6B. Brain activity in medial prefrontal cortex (mPFC) shows high specificity for chronic back pain. Magnitude of mPFC regional activity (as identified in chronic back pain patients) across 5 groups of subjects. Each symbol represents an individual subject. The threshold indicated by broken green line distinguishes chronic back pain (CBP) from pelvic pain (CPPS), osteoarthritis (OA), post-herpetic neuralgia (PHN) for spontaneous pain, and healthy subjects for acute pain (healthy) at an accuracy greater than 90%. The number of subjects studied in each group is indicated above.

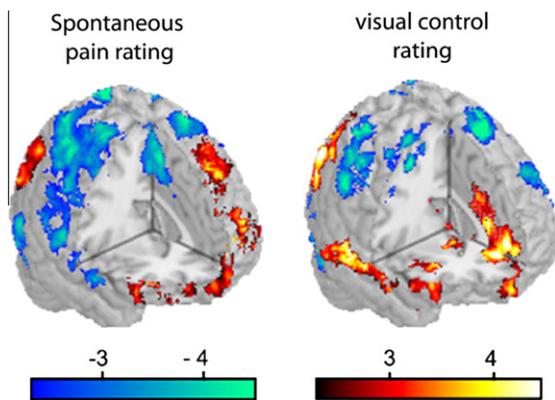

Fig. 7. Intensity of ongoing chronic postherpetic neuropathy pain changes brain activity and thus cognitive processing in a complex pattern, for pain and non-pain tasks. The figure is adapted from a study [39] in which postherpetic neuropathy patients were studied before and after lidocaine application on the painful skin. Each patient was scanned at 3 time points relative to the drug therapy. In all cases the patients performed 2 different tasks: in the pain task they continuously rated the fluctuations of their spontaneous pain (left), and in the visual task they rated fluctuations of a bar varying in time (right). The relationship between brain activity and intensity of ongoing pain was determined using a covariate analysis, in which the related pain intensity for each functional magnetic resonance imaging (fMRI) scan was used to determine the effect of this parameter on brain responses. Across subjects and across all scans, average variation of brain activity is displayed for both tasks. The presence of the chronic pain effects activity in both tasks across large brain areas, rather similarly, increasing activity in some areas (red) and decreasing them in others (blue).

mechanical central sensitization but not thermal, or to technical differences? Still, the lack of evidence for thermal hyperalgesia in chronic back pain seems convincing. On the other hand, when brain activity is contrasted for thermal pain between healthy controls and chronic back pain patients, we observe NAc activity distinguishing between the groups [11]. Moreover, the difference in NAc activity between the groups could be attributed to its phasic response at the end of a thermal stimulus, with healthy subjects showing a signal that reflects prediction of reward, whereas the patients showing a signal that is instead more consistent with a lack of predicted reward and even perhaps a disappointment. These NAc responses reflect that chronic pain patients anticipate

analgesia from acute pain and, in this way, the value associated with acute pain is distorted in these patients. In fact, this reversal of signal was strong enough that it distinguished the groups at accuracy of more than 90%. The result is remarkable because it is independent of the subjective pain perception. Thus, this distorted assessment of analgesia is not captured in the conscious pain ratings; instead it should be regarded as a subconscious evaluation that must, in turn, color subsequent actions/decisions.

In search of a brain source for the distorted NAc activity, we examined its connectivity to the rest of the brain in both groups. The identified networks were distinct. In healthy subjects, NAc was mainly correlated to the insula, whereas in the patients it was better correlated with mPFC. Moreover, the strength of connectivity between NAc and mPFC was in direct proportion of the amount of back pain that any given patient reported experiencing (Fig. 9). The strength of this across patient correlation of connectivity implies that the more someone is in back pain, the more information is shared between the 2 brain regions; this parameter can also be viewed as an objective measure that can identify the magnitude of back pain with a paradigm whereby the participant is not even aware of what is being measured. The patients were basically signaling that they prefer to keep this acute pain on their skin and are disappointed when it ceases, although their conscious rating of the painful stimulus and brain activity for the pain perception were identical to healthy subjects' perception and brain activity. To capture the impact of this NAc signal on perception, we examined ratings of spontaneous pain in another group of chronic back pain patients during the thermal stimulation and could demonstrate that this stimulus was actually analgesic to their spontaneous pain, to the surprise of the patients and only when patients specifically directed their attention to their own pain (Fig. 10). The mechanisms regarding the transition of NAc from sharing information with insula (healthy subjects) switching to sharing information with mPFC comes (chronic pain patients) remain to be studied. Also, how prevalent this switch is across different chronic pain groups, its relationship to conscious versus unconscious events, and a myriad related questions remain to be addressed. The study, in a sense, demonstrates that one can explore the impact of the emotion of pain outside of the sensory/affective, entangled, perception representation, and that the components of the Cartesian soul can be broken into their constituent subconscious parts in the brain, which in turn influence conscious behavior outside or independent of sensory representation.

4. Distortions of brain anatomy in chronic pain

About 10 years ago, we presented the first evidence for brain metabolite abnormalities, as measured by magnetic resonance spectroscopy (MRS), in chronic back pain patients [44–46]. We predicted in those studies that brain gray matter should show atrophy, and in 2004 we published the first results for brain gray matter distortions in chronic back pain [7]; since then, a steadily accumulating literature has been documenting evidence for brain morphological changes in multiple clinical pain conditions: back pain [90], fibromyalgia [54,57,65,92], CRPS [40], knee osteoarthritis [87], irritable bowel syndrome [14,28], headaches [55,89,91,104], chronic vulvar pain [93], and in female individuals with menstrual pains [102], as well as in animal models of chronic pain [70,96]. The evidence for metabolic changes with chronic pain has come more slowly, as only a handful of studies have been done on the topic [36,47,103]. Metabolic and morphological approaches are complementary techniques and comparisons of outcomes with both should enhance understanding of underlying mechanisms. However, MRS remains technically underdeveloped and fraught with confounds, as a result its impact on brain neuroscience in general has lagged.

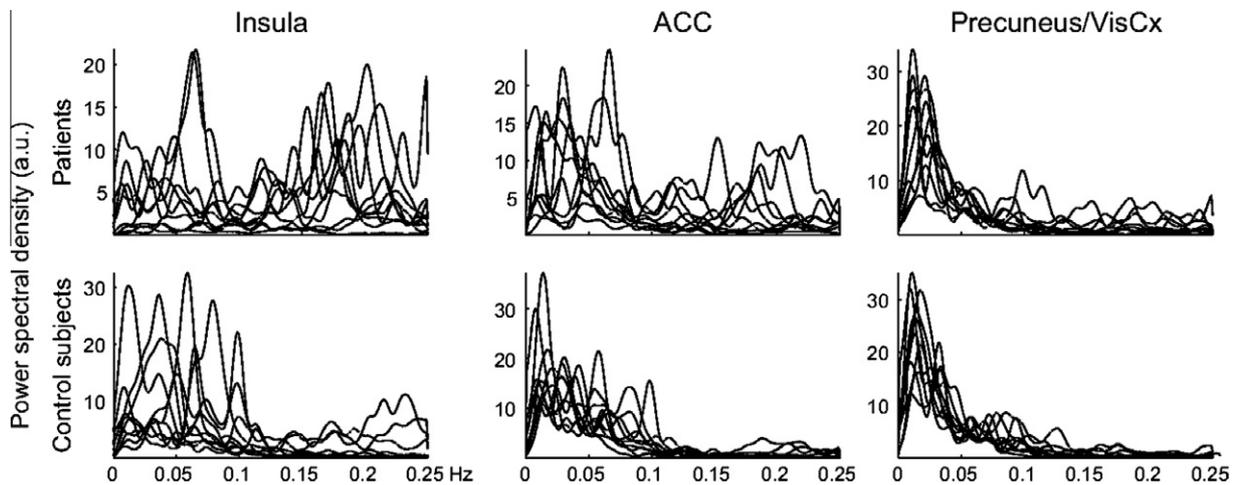

Fig. 8. In chronic pain patients and in the absence of any specific task (resting state) activity in the insula and anterior cingulate, but not in the precuneus/visual cortex, fluctuate at higher frequencies than in control subjects. Power spectral density as a function of frequency is shown for each individual subject. Figure from [66].

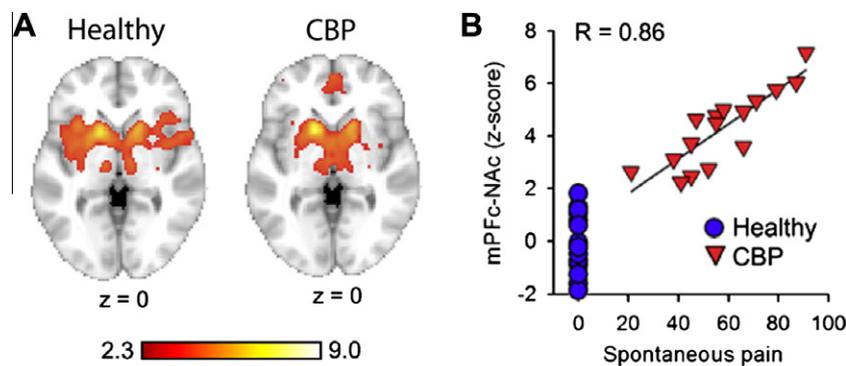

Fig. 9. Distinct functional connectivity between nucleus accumbens and the rest of the brain are observed in chronic pain patients in contrast to healthy subjects. This shift in connectivity is tightly correlated to the magnitude of back pain reported by the patients. (A) Healthy: Functional connectivity between nucleus accumbens and the rest of the brain in healthy subjects. We observe extensive bilateral insula involvement. (A) CBP: Functional connectivity for nucleus accumbens in chronic back pain patients. Functional connectivity is shifted away from the insula to medial prefrontal cortex. (B) Strength of connectivity between nucleus accumbens and medial prefrontal cortex in relation to the magnitude of back pain reported. Each red symbol is an individual chronic back pain patient; blue circles are healthy controls. The higher the magnitude of spontaneous pain of back pain the stronger is the correlation between mPFC and NAc, implying more information sharing between these 2 brain regions. Figure adapted from [11].

Fig. 11 illustrates some of the pain conditions for which brain gray matter properties have been reported to be abnormal. Our initial morphometric study and a number of subsequent studies demonstrate that specific regional gray matter decreases correlate with duration of chronic pain, its intensity, and even the interaction between both factors [7,40,57], suggesting that the properties of the clinical conditions are influencing brain morphology. Brain morphometry studied in fibromyalgia patients by multiple researchers [18,54,57,65,92,109] have shown a regional decrease in gray matter density [18,57,109], whereas others show an increase [92], and 1 study shows no change at all [54]. Another study failed to demonstrate a relationship among pain intensity, duration, and gray matter density, and the authors interpret the lack of these relationships as evidence that observed anatomical abnormalities may be used as evidence for a brain predisposition for chronic pain [18]. Such variability of outcomes is unlikely to be a reflection of the patients studied. Instead it is more probably because of the fact that morphometric studies are complicated and that subtle technical differences can bias outcomes; the most important confound is integrity of acquired anatomical MRI scans, in which a few poor brain images may lead to opposite conclusions. Inadequate registration and/or segmentation can also give rise to false outcomes. Unfortunately there are no standard techniques for identifying

such errors, and very few groups perform quality control checks on acquired brain images. Using strict quality control procedures, we have now studied this question across multiple chronic pain patient groups in contrast to healthy subjects; our results indicate that in chronic back pain, osteoarthritis, and CRPS, we observe only decreased regional gray matter density, and these decreases are specific to each type of chronic pain (manuscript in preparation). The most important message from these gray matter studies is the suggestion that distinct chronic pain conditions have differential impacts on brain anatomy. A number of groups recently reported on the reversibility of brain morphometric changes with pain relief (Fig. 12), and most agree that at least some brain regional morphometric properties do reverse when pain is substantially relieved [48,78,87]. These early reports need to be examined more comprehensively and are yet important, as they indicate that at least some of the morphological changes must be a direct consequence of the presence of the pain, and most likely the underlying mechanism is based on synaptic plasticity that tracks the impact of the pain on the brain.

Mechanisms responsible for brain gray matter morphological changes remain unclear [67]. The available evidence suggests multiple mechanisms because morphological changes can be observed at early time points from initial injury as well as after long periods from

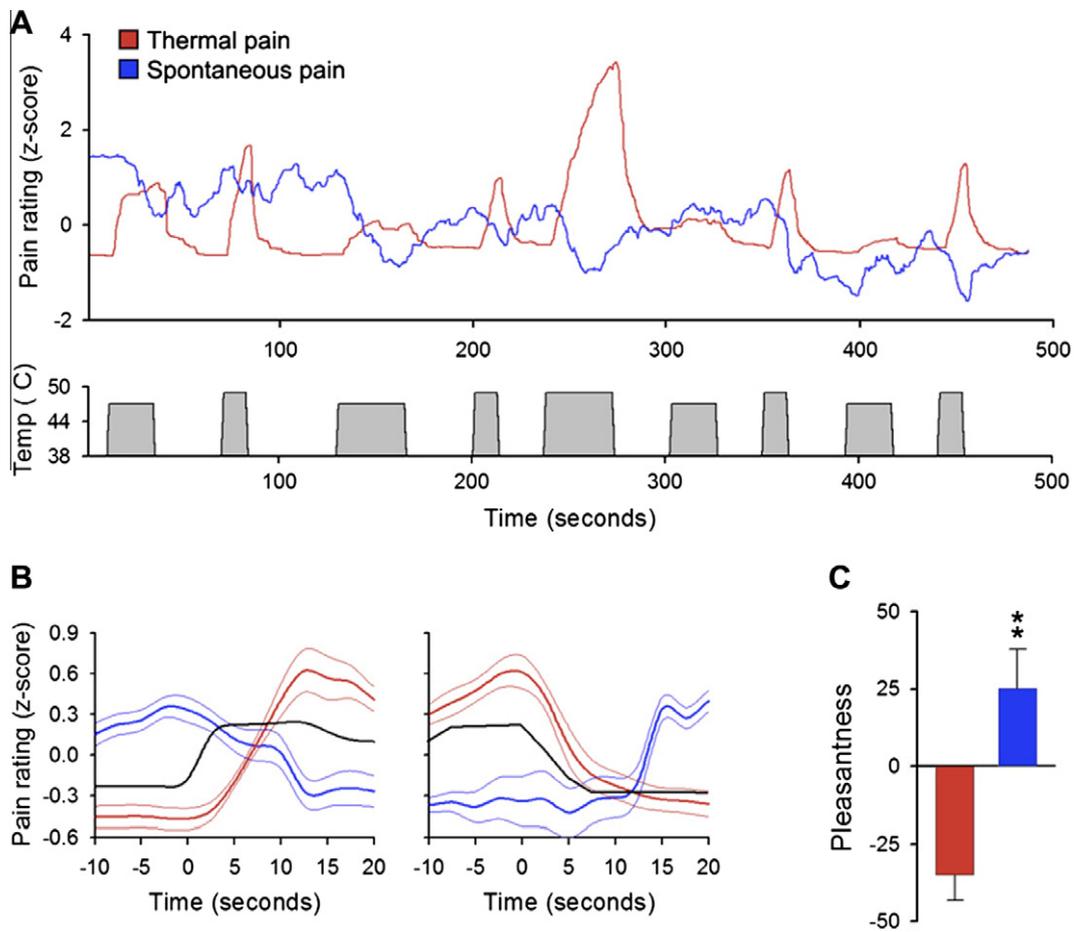

Fig. 10. Chronic back pain patients report a decrease in the magnitude of their back pain during a thermal painful stimulus applied to the skin on their back. They seem to only realize this fact when they are specifically instructed to attend to their own back pain. A. Group average ratings of either the magnitude of thermal painful stimulus (red) or spontaneous fluctuations of back pain (blue), for a stimulus pattern shown below (grey) that is unpredictable in intensity and duration. Every time the stimulus is felt painful it seems to induce a decrease in spontaneous pain. B. Average stimulus pain perception (red) and spontaneous back pain perception (blue) relative to start and end of thermal stimulus (black). Rating of the stimulus intensity and back pain were done separately. C. When the back pain patients rate the stimulus, they judge the experience as unpleasant (red). But for the same stimulus when they rate their own back pain the experience is judged to be significantly more pleasant (blue). Figure adapted from [11].

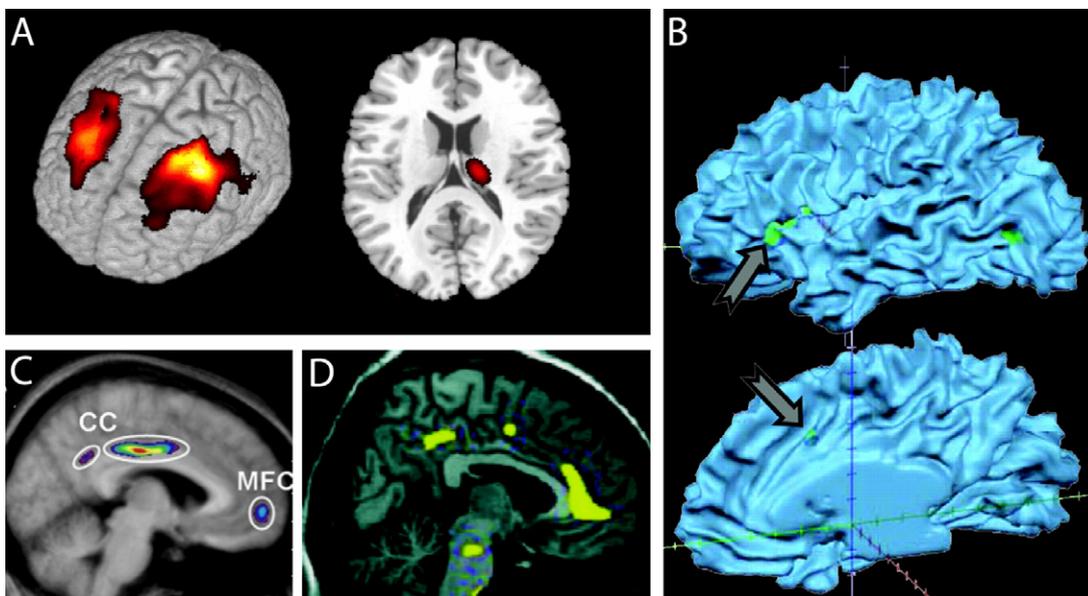

Fig. 11. Brain regional gray matter decreases in a number of chronic pain conditions. (A) Bilateral dorsolateral prefrontal cortex and unilateral thalamic gray matter decreases in chronic back pain, from [7]. (B) Insula and cingulate cortex gray matter decreases in irritable bowel syndrome, from [26]. Multiple brain regions show decrease gray matter density in (C) fibromyalgia, from [57], and in (D) tension headache, from [91]. The illustrated data are the earliest reports of brain morphological changes in various pain conditions. The list of additional pain conditions impacting brain anatomy is expanding very quickly.

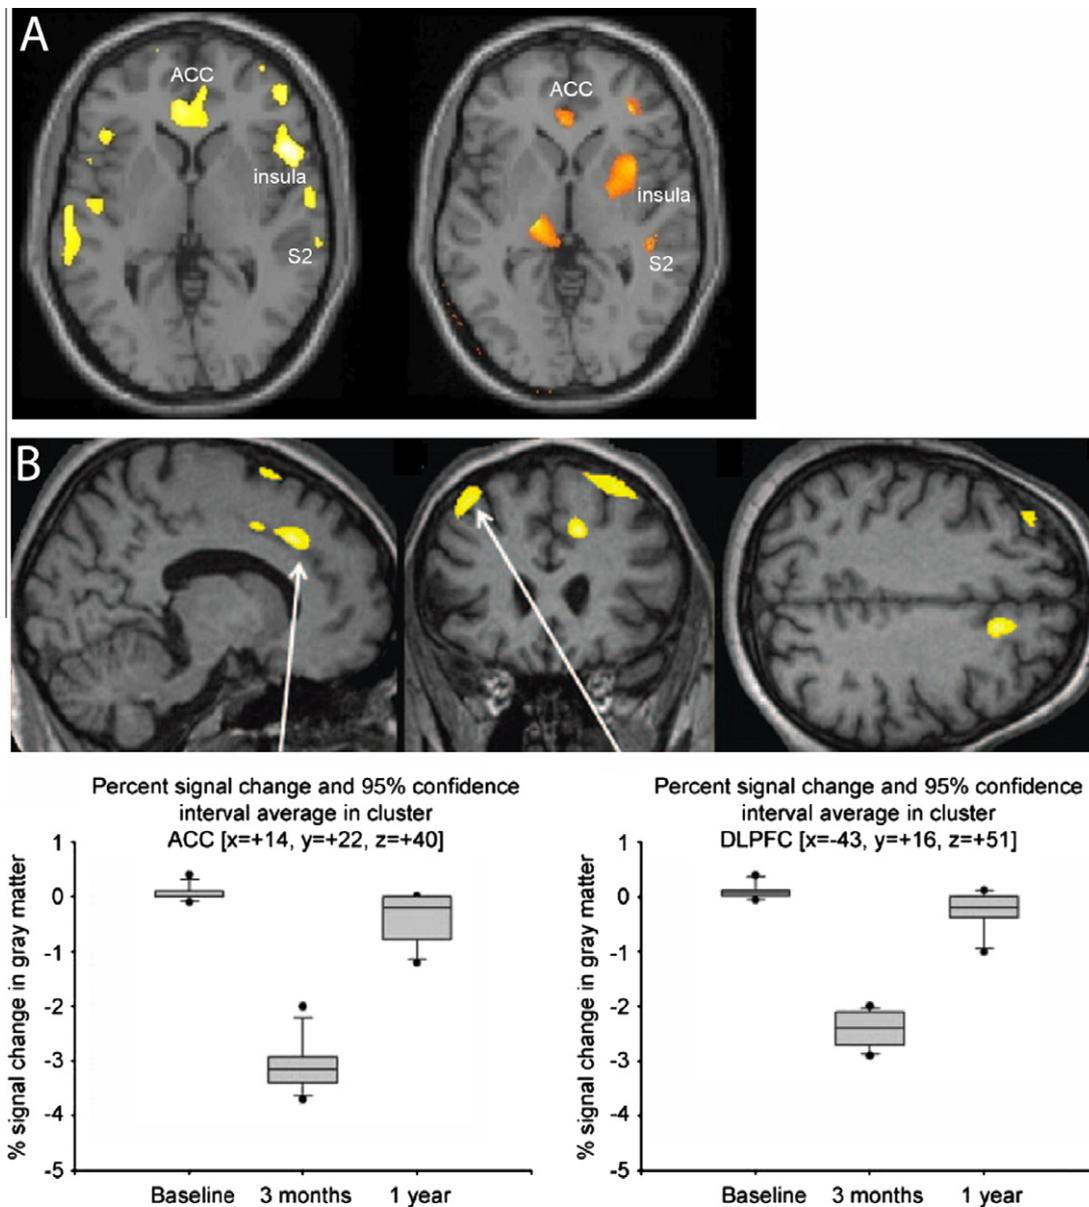

Fig. 12. Evidence for brain gray matter density recovery with cessation of chronic pain. (A) Left panel shows brain regions decreased in gray matter density in chronic osteoarthritis patients. Right panel shows brain regions where gray matter density increases following joint replacement and cessation of pain in osteoarthritis patients. Generally similar brain regions seem to changes with the presence and cessation of chronic pain. Adapted from [87]. (B) Brain regional morphometry changes in post-traumatic headache. Gray matter density changes are shown for 2 brain regions in patients that develop chronic pain (3 months) and 1 year later when the pain subsided (1 year). In both areas, gray matter signal recovers to original levels when pain symptoms subside. Adapted from [78].

injury, best illustrated in 2 animal studies [70,96]. If regional gray matter changes are more than just a reflection of local extracellular changes in water, which may occur based on changes in concentration of channels of proteins within neurons and/or glia, then properties of axons connected to the regional neurons involved should change as well. In a very simple way, if decreased gray matter density corresponds to neuronal death, then underlying white matter density or connectivity should also be modified reflecting such changes. We probed this issue by examining the integrity of brain white matter in chronic pain patients and also by relating gray matter changes to underlying white matter properties in patients with complex regional pain syndrome (CRPS) relative to matched healthy controls [40]. White matter properties can now be studied by diffusion tensor imaging (DTI). This technology has dramatically matured in the last few years and provides powerful tools with which one can pose exciting new questions about axonal properties of the human

brain, regarding local integrity (based on measures of fractional anisotropy, FA) as well as the properties of white matter tracts (quantified by probabilistic tractography) [74]. Using a combination of voxel-based morphometry and DTI, we could demonstrate regional decreased gray matter density and regional white matter abnormality demonstrated by local decrease in FA in the patients. Moreover, both FA value decreases and gray matter density decreases were accompanied by changes in white matter connectivity. However, changes in connectivity were target specific, with some projections showing increases and other decreases. These results again suggest that multiple complex mechanisms underlie brain morphometric changes, some of which may be regarded as markers for predisposition for the observed chronic pain condition. In addition, we documented the first evidence for global reorganization of the CRPS brain. We first showed a strong linear relationship between whole neocortex gray matter volume (after correcting for age

effects) and whole neocortex white matter mean FA values across healthy subjects. To our knowledge, this is the first evidence for such a global relationship, and it implies that myelin properties or axonal density properties adjust in relation to brain size in normal subjects. This relationship was completely disrupted in CRPS patients, in whom we could find no significant relationship between whole-brain FA and neocortical gray matter volume. Therefore, across the whole brain, the gray matter to white matter relationship is disrupted in these patients, implying that changes in 1 of these compartments is not being properly compensated for in the other compartment (Fig. 13), which in turn implies that, above and beyond the local gray and white matter changes that we documented, there are also across the brain large-scale morphological changes associated with chronic pain. Mechanisms and parameters controlling this larger scale reorganization also remain to be studied.

5. Learning, and forgetting, and a brain circuitry model for transition to chronic pain

We have previously argued that chronic pain can be viewed as a state of continuous learning coupled with reduced opportunity for

forgetting [2,3,72]. Thousands of studies illustrate the potency of painful events to induce learning in which mechanisms of learning are investigated using Pavlovian paradigms, the majority of which use pain (electrical shock) as the unconditioned stimulus with which various events are associated. Such studies repeatedly show that single painful stimuli are learned and remembered for weeks and months. Such studies also illustrate that once the associated learning occurs, the extinction of this association requires repeated exposure of the organism to the conditioned stimulus in the absence of the painful event. As chronic pain is fundamentally a state of continuous presence of pain, we can then conclude that it is also a state of continuous acquisition of associations with random events surrounding the organism, especially at time points when the pain is high. Moreover, as the pain remains unremitting, the organism does not have the opportunity of extinguishing these random associations, which requires frequent exposure to the same environment in the absence of pain. In fact we suggest that the contradiction between the subject's conscious knowledge that the pain is not associated with the environment and the brain circuitry that continuously make such associations may be the core cognitive/emotional source of the suffering that chronic pain patients experience.

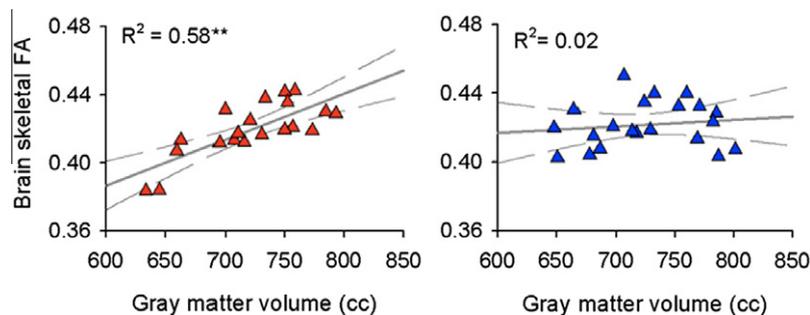

Fig. 13. Whole-brain relationship between gray and white matter is disrupted in chronic complex regional pain syndrome subjects. Left panel shows that white matter fractional anisotropy (FA; measured for group average skeleton which insures that the tissue examined has 95% probability of being white matter) is correlated to total neocortical volume of the brain (after correcting for age effects). Right panel depicts similar data in complex regional pain syndrome patients, and shows that the relationship is destroyed. In both panels, each symbol represents the brain of a subject: red indicates healthy controls; blue indicates patients. Adapted from [40].

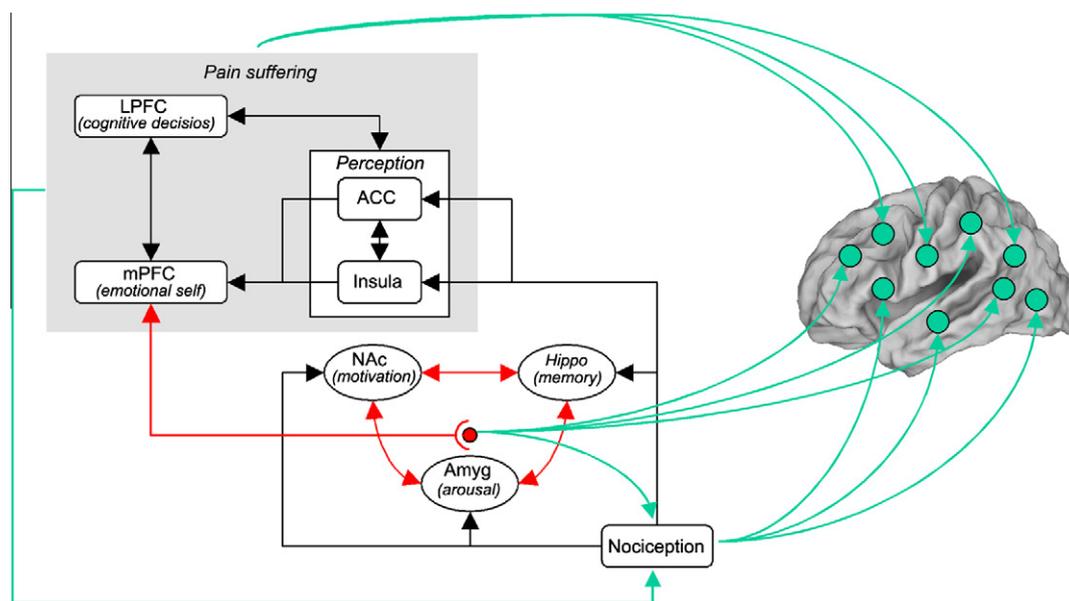

Fig. 14. A model regarding brain circuitry involved in the transition from acute to chronic pain. Nociceptive information, perhaps distorted by peripheral and spinal cord sensitization processes, impinges on limbic circuitry (Hippo, hippocampus; NAc, nucleus accumbens; and Amyg, amygdala). The interaction of limbic circuitry with prefrontal processes determines the level at which a certain pain condition transitions to a more emotional state. The limbic circuitry also provides learning/modulation signals to the rest of the cortex inducing functional and anatomical distortions that reflect the suffering and coping strategies of specific chronic pain conditions. Nociceptive signals also provide the brain with modulatory signals, and are in turn controlled by the state of suffering of the individual as well as limbic changes in arousal and motivation, through descending modulatory pathways.

Within this theoretical construct of chronic pain, we can now posit a general model of the brain circuitry regarding the transition from acute to chronic pain, based on the evidence presented above and coupling these observations to anatomical and physiological observations (Fig. 14). We first emphasize that nociceptive information accesses the cortex through multiple pathways and not just by the spinothalamic projection (the majority of human brain imaging results continue to be interpreted in relation to the spinothalamic pathway). Even within the spinothalamic system medial thalamic cortical projections access large portions of the frontal cortex targeting mainly superficial layers [73]. This pathway is a reticulo-thalamocortical network that relays widespread nociceptive information to widespread cortical regions and most likely provides modulatory influences on large prefrontal cortical processes. Other nociceptive pathways such as the parabrachial-amygdala projections, spinal basal ganglia projections, spinal hypothalamic and spinal prefrontal projections [17,38,56,77] and other monosynaptic and polysynaptic spinal-reticular-cortical projections provide ample opportunities for nociceptive information accessing various cortical circuitry and modulating such circuitry as a function of a continuous barrage of nociceptive inputs associated with chronic pain. Thus, continuous nociceptive input to supraspinal targets both reorganizes memories and their associations within the cortex, and reorganizes motivational and memory consolidation properties of the limbic cortex.

The human functional brain imaging studies for chronic pain point to the recurring theme that chronic pain conditions engage preferentially medial prefrontal cortical areas as well as subcortical limbic regions, especially portions of the dorsal and ventral basal ganglia [16], amygdala [76], and hippocampus [60]. Even though different types of chronic pain and different perceptions in such patients engage distinct cortical and subcortical regions, by and large, all of them show a shift away from brain regions engaged in sensory processing of pain toward regions encoding emotional and motivational subjective states. The continuous activation of these limbic/emotional structures must result in shifts in valuation (some of which are reviewed above), and these shifts would in turn modulate cortical learning and memory processes [34,108]. Moreover, the shift in valuation in turn influences nociceptive processing in the spinal cord, coupled with or further strengthened by shifts in prefrontal cortical emotional shifts. These descending modulatory systems provide yet another source of spinal cord central sensitization, as demonstrated in animals models [37], and are probably more important in human chronic pain conditions.

The details of the mechanisms across the brain network involved in chronic pain remain fuzzy, will undoubtedly continue to change with new observations, and certainly require more studies. As a result, the model that we present here (Fig. 14) is intentionally kept imprecise and is designed to indicate only a global construct.

6. Summary and conclusions

The functional imaging studies summarized here first show that the subjectivity of pain can be captured by objective markers of brain activity, and that the general approach of searching for brain events closely related to the consciousness of pain provides a powerful concept with which acute and chronic pain can be studied and contrasted with each other. The approach even results in unraveling brain unconscious events that color motivation and valuation independent of conscious perception as a consequence of living with chronic pain. The comparison between different chronic pain conditions reveals that underlying brain activity is distinct with a general trend toward engaging limbic and

paralimbic structures. The morphological studies show that the brain structure undergoes changes at multiple spatial and temporal scales, which are for the most part specific to the type of chronic pain studied. That some of these changes are reversible by cessation of chronic pain speaks to the specificity of the processes and also demonstrate that chronic pain may in fact be used as a unique tool with which the dynamics of brain plasticity can be studied at multiple spatial and temporal scales.

Based on the functional and morphological reorganization of the brain in chronic pain, we advance a brain circuitry model for this transition in which the primary drive is assumed to be the ability of pain to induce long-term memories by reinforcing learning mechanisms. We do not want to disregard the myriad of peripheral, spinal cord, and brainstem descending modulatory changes that have been described to accompany persistent or chronic pain, as documented in animal models for such conditions. Instead we think that these peripheral and central sensitization events simply exaggerate the reorganization of limbic circuitry that in turn reflect their effects on prefrontal cortical evaluation of pain as well as provide the learning signals with which interactions between various cortical circuitry adapt to the suffering and coping that is specific to each clinical chronic pain condition.

Correspondences between physiological and morphological reorganization, as well as with metabolic changes, should point to specific cognitive and sensory and motor ability changes that undoubtedly accompany distinct chronic pain conditions in specific patterns. We have taken some small steps in this direction [6,98]; however much more needs to be done, as the array of cognitive impairments documented in chronic pain is large [50] and their unique contributions and relations to specific clinical cases remains to be systematically approached.

Anatomical and functional specificity of the brain in distinct chronic pain conditions perhaps seems as a new complication. However it suggests the possibility of unique therapies by targeting the underlying specific pathways for each type of chronic pain (see, for example [23,72,100]). Moreover, it suggests that such therapies can be tested with very specific, objective brain-derived markers [34], even bypassing conscious reports.
